INTERIM REPORT

To: Vincent P. Drnevich, Director
Joint Highway Research Project

From: W. F. Chen, Research Engineer
Joint Highway Research Project

January 23, 1992

Project No: C-3636U
File: 6-14-21

Attached is the second Interim Report on the HPR Part II Study entitled, "Embankment Widening and Grade Raising on Soft Foundation Soils: A Sensitivity Analysis of the Parameters for a Cap Plasticity Model". This phase was conducted by Scott J. Ludlow under the direction of Wai-Fah Chen, Philippe L. Bourdeau and C. William Lovell.

This report is forwarded for review, comment and acceptance by the INDOT and FHWA as partial fulfillment of the objectives of the research.

Respectfully submitted,

W. F. Chen
Research Engineer

ACKNOWLEDGEMENTS

The author wishes to express his appreciation to Professor C. W. Lovell for providing the opportunity to work on this project.

Thanks are also due Professor H. L. Michael, Director, Joint Highway Research Project, and other members of the Joint Highway Research Board for their continued support of the county soil mapping project.

The substantial contributions of Dr. Arvind Chaturvedi for providing valuable discussion and opinions to the report are greatly appreciated.

The author also wishes to acknowledge D. Yang for skillfully drafting the Engineering Soil Map of Washington County and other figures included in this report, Rita Pritchett for typing the classification test results presented in Appendix A, and Will McDermott and Marian Sipes for formatting the text and final preparation of this report.

ENGINEERING SOILS MAP

OF

WASHINGTON COUNTY, INDIANA

INTRODUCTION

The engineering soils map of Washington County, Indiana which accompanies this report was prepared by airphoto interpretation techniques using accepted principles of observation and inference. The 7-inch x 9-inch aerial photographs used in this study, having an approximate scale of 1:20,000, were taken in the summer of 1938 for the United States Department of Agriculture and were purchased from that agency. The attached Engineering Soil Map was prepared at a scale ratio of 1:63,360 (1 inch = 1 mile).

Standard symbols, which were developed by the staff of the Airphoto Interpretation Laboratory of the School of Civil Engineering at Purdue University, were employed to delineate landform-parent material associations and soil textures. The text of this report represents an effort to overcome the limitations imposed by adherence to a standard symbolism and map presentation.

Extensive use was made of the Agricultural Soil Survey of Washington County published in 1988 (1). It was particularly useful as a cross-reference to check soil boundaries, and to locate gravel pits and ponds which were not present on the 1938 aerial photographs.

* Numbers in parentheses refer to items in the list of references.

The map and report are part of a continuing effort to complete a comprehensive soil survey for the state of Indiana. Included on the map is a set of subsurface soil profiles which illustrate the approximate variation that is anticipated in each landform-parent material area. The profiles were constructed from information obtained from agricultural literature and from boring data collected from roadway and bridge site investigations (27-38). Boring locations are shown on the map. Appendix A contains a summary of classification test results for these locations.

The text of this report supplements the Engineering Soil Map. Furthermore, it includes a general description of the study area, a description of the different landform-parent material regions, and a discussion of the engineering considerations associated with the soils found in Washington County.

The predominant soils associated with each landform-parent material classification are covered in the discussion of the different landforms in the county. The physical, chemical, and engineering index properties of these soils are included in Appendices B and C.

DESCRIPTION OF THE AREA

GENERAL

Washington County is located in southern Indiana as illustrated in Figure 1, and is about midway between the eastern and western boundaries of the State. The County is bordered by eight other counties. These are Jackson County on the north, Scott County and Clark County on the east, Floyd County on the southeast, Harrison County on the south, Crawford County on the southwest, Orange County on the west, and Lawrence County on the northwest. Salem, the county seat, is located along the West Fork of Blue River in the central part of the county, approximately 83 miles south of Indianapolis.

The northern boundary of the county lies about 70 miles south of Indianapolis and the southern boundary about 30 miles north of the Ohio River. The county is about 22 miles wide (east-west) by 23 miles long (north-south) and has a land area of 330,624 acres, or 517 square miles.

Washington County is served by one railroad and by a small airport, which is located one mile west of Salem. Washington County also has about 112 miles of federal and state highways and 890 miles of all-weather county roads. Some of the county roads are paved (1).

The population of Washington County was approximately 21,920 in 1980. At that time Salem had a population of about 5,500, which is 25 % of the total population. The population of Washington County increased 8.8 percent since 1970, and this trend is expected to continue in the future. The population density in 1980 was 42 people per square mile. A population summary of the important cities and towns in the county is given in Table 1.

Farming is the leading enterprise in the county. Cash grain and livestock are the major agricultural products. The major kind of livestock is beef cattle. Woodland makes up about a third of the county. From 1969 to 1974, the acreage of cropland increased by 17.4 percent,

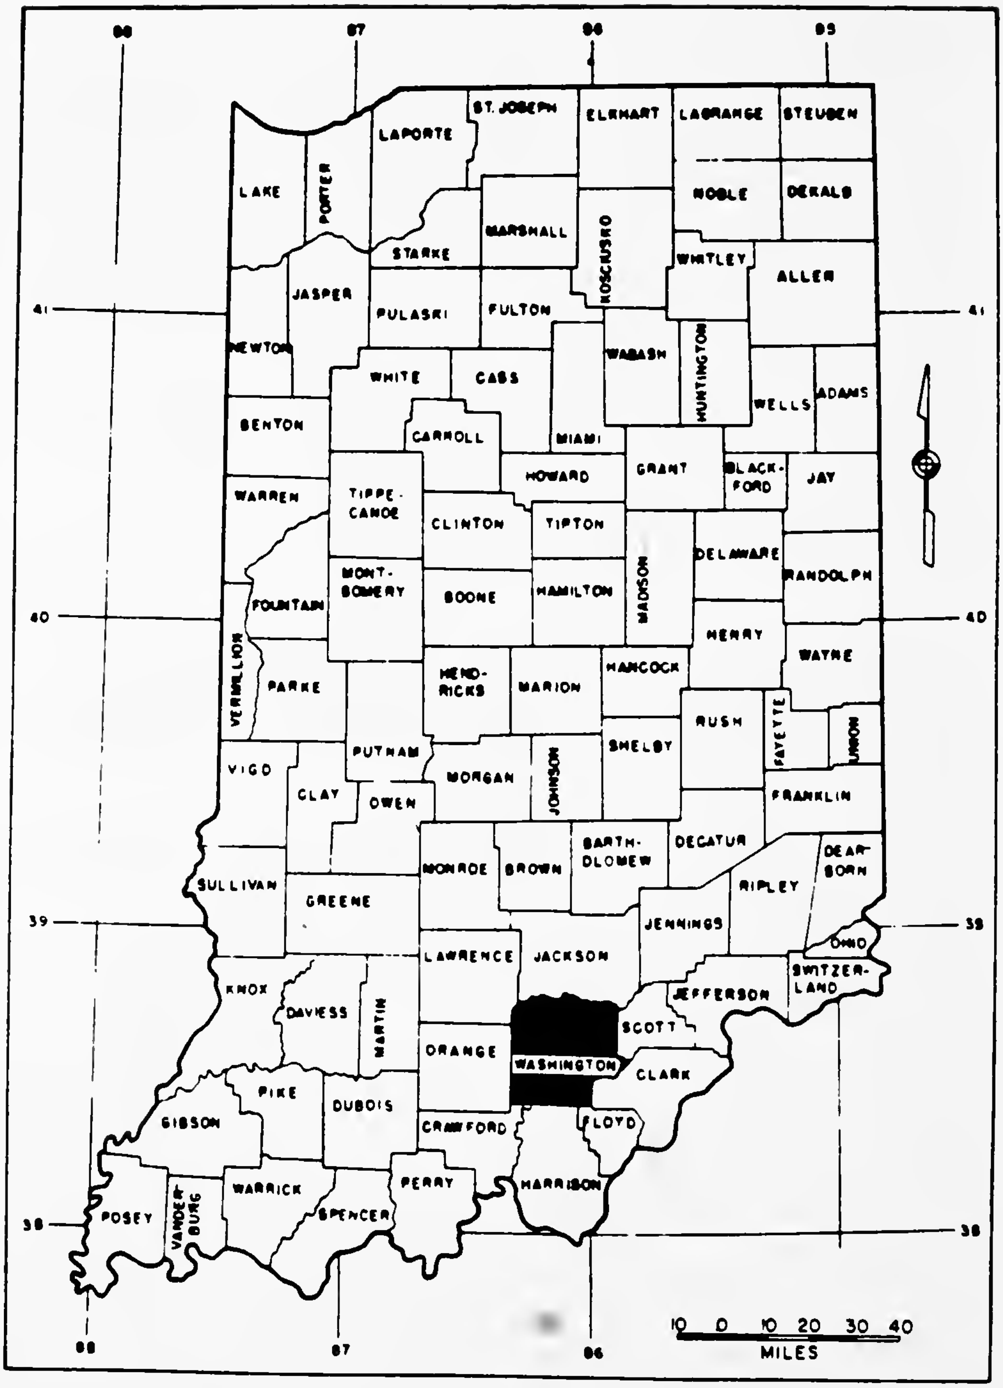

FIGURE 1. LOCATION MAP OF WASHINGTON COUNTY

that of pasture decreased by 7.6 percent, that of idle land decreased by 16.5 percent, and that of woodland decreased by 16.1 percent. This trend is expected to continue. About 7460 acres in the county, or 2 % of the total acreage, is urban or built-up lands. The acreage used for urban development is expected to increase (1).

CLIMATE

The climate of Washington County is typically continental. The humidity is high and the temperature change is remarkable seasonally. Table 2 and 3 give data on temperature and precipitation for this area as recorded at Salem, Indiana.

In winter the average temperature is 33 degrees F, whereas the average temperature in summer is 74 degrees F. In this county, the highest and lowest recorded temperatures are 105 and -32 degrees F. The total annual precipitation is 43.35 inches, and 53 percent of this usually falls in April through September. Thunderstorms occur on about 45 days each year (1).

DRAINAGE FEATURES

Drainage features of Washington County are shown in Figure 2, Drainage Map – Washington County, Indiana, prepared by the Joint Highway Research Project, Purdue University, 1952. The county is drained by four river systems, principally the three Forks of Blue River. The northern and eastern parts are drained by the East Fork of White River either directly or by way of the tributary Muscatatuck River and its branches; a small area in the western part is drained by the headwater branches of Lost River, which also eventually flows into the East Fork; and a very small area in the southeastern part (three square miles) is drained

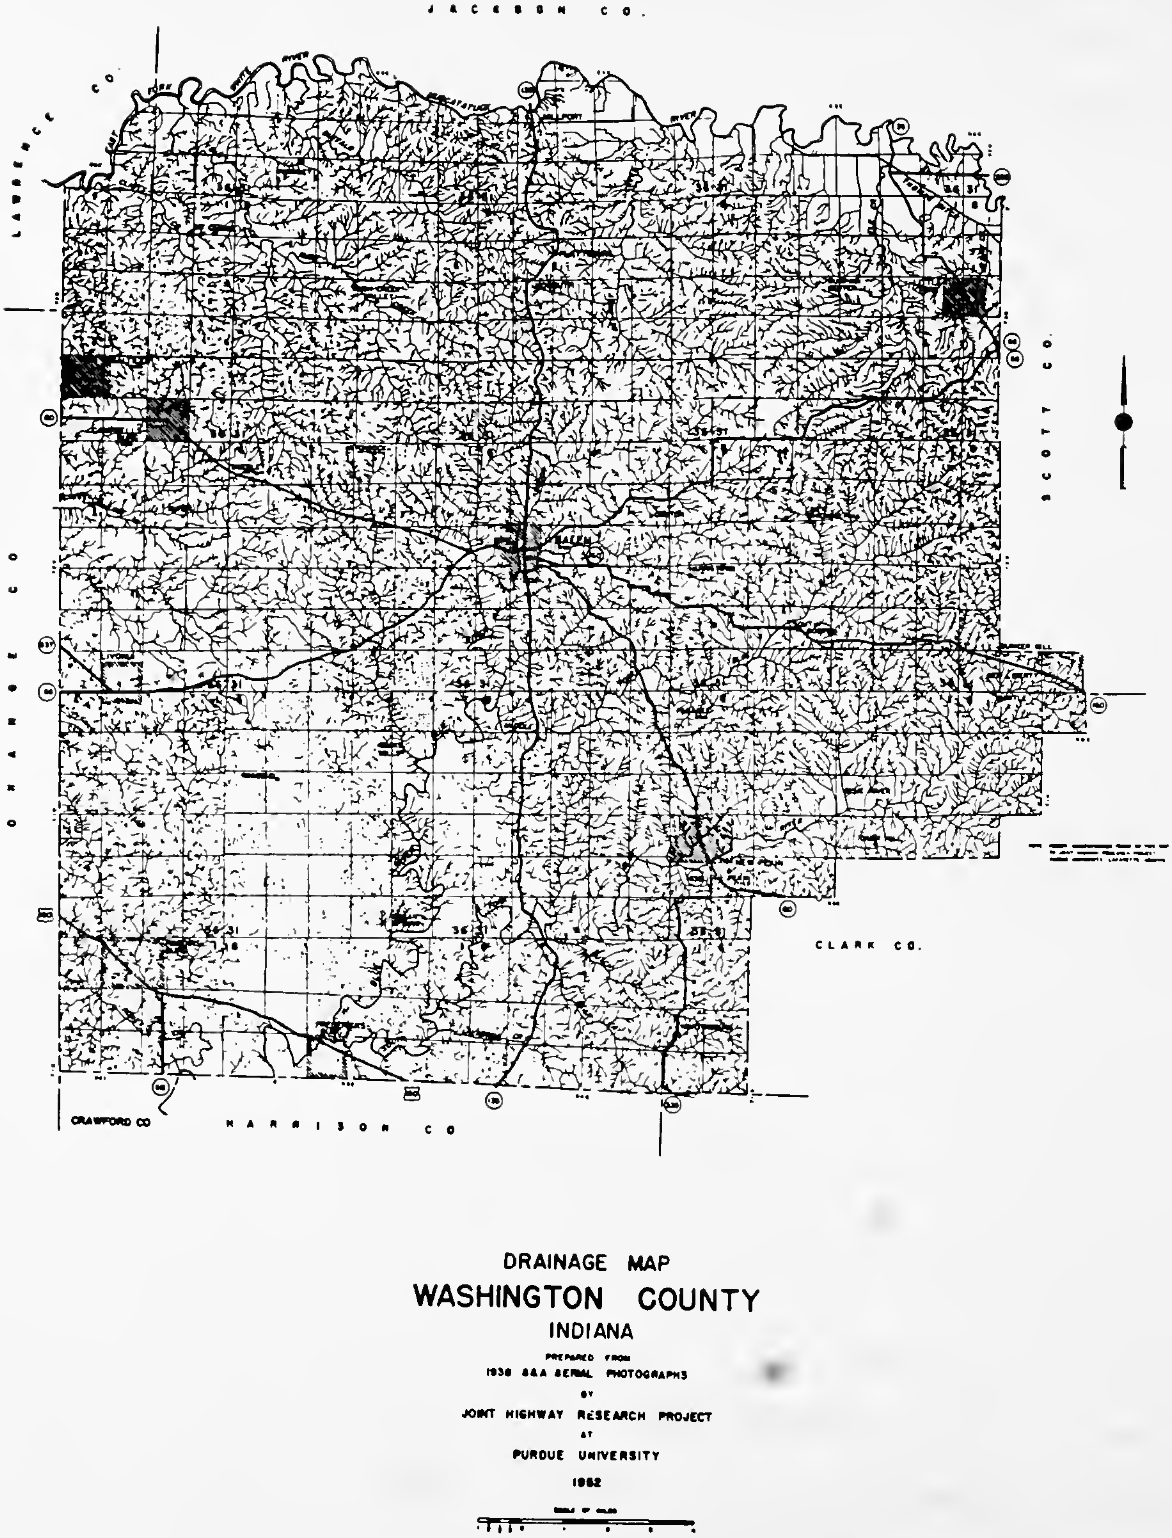

FIGURE 2. DRAINAGE MAP OF WASHINGTON COUNTY (14)

by the headwater branches of the Muddy Fork of Silver Creek. The rest of the surface water in the county drains to the southwest through the three Forks of Blue River (see Figure 2).

The waters of Lost River and the East Fork of White River empty into the Wabash River to the west, and then into the Ohio River, whereas the waters of the Blue River and the Muddy Fork of Silver Creek empty directly into the Ohio River to the south (2). Numerous sinkholes occur in the southern and northwestern parts of the county. Surface water enters the sinkholes and drains through caves into some of the streams.

WATER SUPPLY

The water resources are very limited in Washington County. Washington County lies within two watersheds of Indiana as shown in Figure 3. The northern part belongs to East Fork of White River watershed, whereas the southern part belongs to the Minor Ohio River watershed. For surface water supply, only the East Fork of White River, the Muscatatuck River, and the lower waters of the Blue River system are large enough to provide supplies of municipal and industrial water throughout the year.

Groundwater is another source of water supply. Washington County is located in two groundwater sections. They are Devonian and Mississippian Siltstone and Shales Section and Mississippian Limestone Section (See Figure 4). Wells are driven to obtain reliable water supply in most places. In most wells driven in bedrock, water is probably derived from bedding-plane or lithologic-boundary aquifers. In general, the rocks of the Borden Group are poor aquifers. However, one of the most reliable bedrock aquifers is the zone of contact between Borden and Harrodsburg rocks. (Please refer to the section on Bedrock Geology for the description of these bedrocks.)

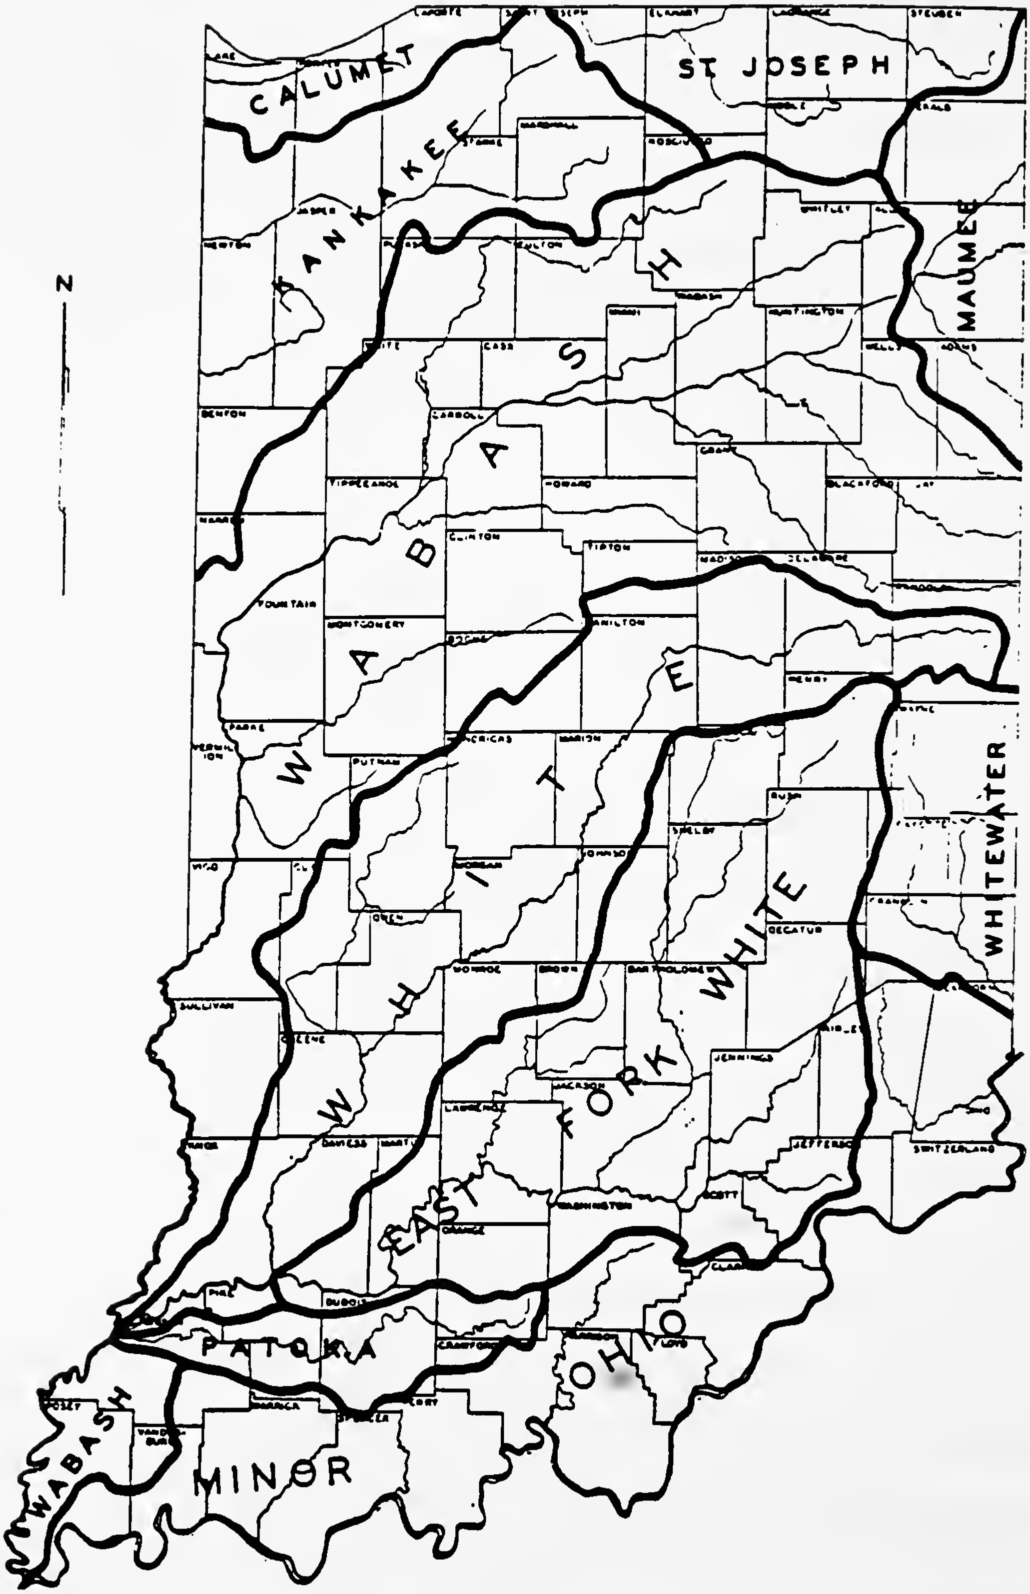

FIGURE 3. MAJOR WATERSHEDS OF INDIANA (15)

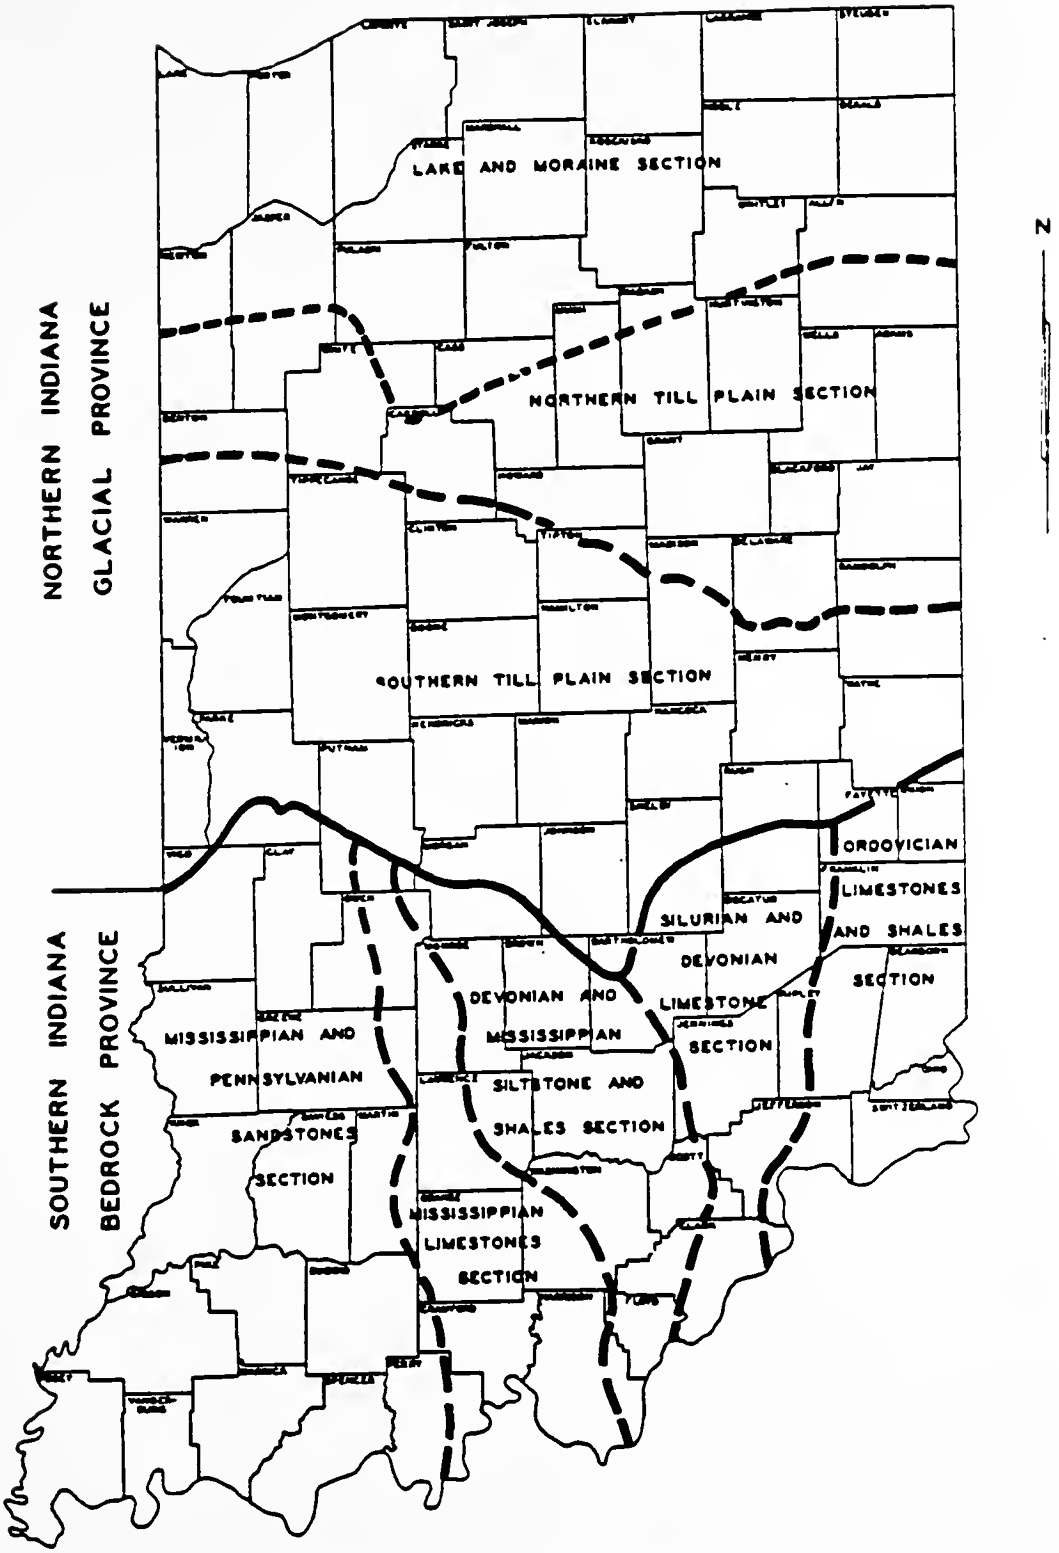

FIGURE 4. GROUNDWATER SECTIONS OF INDIANA (15)

In addition, large quantities of water are stored in some sand and gravel aquifers. The deposit of sand and gravel in the valley of the East Fork of White River probably is the largest ground-water aquifer in Washington County. This deposit, 75 feet thick or more, could yield enough water for industrial, municipal, and domestic use of the surrounding areas.

Although underground water is available in some areas, the water supply is still a major problem in most of the county. Ponds and springs are used as a source of water in many places, but they dry up or stop during periods of drought. In areas of karst topography, soils are underlain by cavernous limestone and are subject to seepage. Therefore, they are not suitable for new ponds. Also, sinkhole ponds in this area are only temporary. On the other hand, lakes and ponds whose floors and sides are of rocks of the Borden Group probably will retain water with very little leakage. At the town of Salem, water is obtained from Lake Salinda and Lake John Hay. The water use summary for Washington County in 1989 is shown in Table 4.

PHYSIOGRAPHY

The State of Indiana can be divided into nine physiographic regions based on surface topographic features. Washington County contains parts of four of these sections: the Scottsburg Lowland, the Norman Upland, the Mitchell Plain, and the Crawford Upland (2). The Scottsburg Lowland occurs in the form of a narrow strip, that is characterized by long, sloping valleys along the streams and a notable lack of steep hills. The Norman Upland is predominantly of sandstone origin and has a rolling and dissected surface. The topography of the Mitchell Plain has two unique features, namely rounded hills and sinkholes. Ponds are also seen due to the temporary blockage of sinkholes. The Crawford Upland is also of sandstone and shale origin. It is dissected and severely weathered (3). These regional physiographic units are illustrated in Figures 5 and 6. With relation to its physiographic situation in the United States, Washington County is a part of the Low Plateau Province.

TOPOGRAPHY

There are 17 quadrangle maps in the USGS 7 1/2-minute series that provide topographic coverage for Washington County. They are the Becks Mill, Borden, Campbellsburg, Fredericksburg, Hardinsburg, Henryville, Kossuth, Little York, Livonia, Medora, Palmyra, Salem, Smedley, South Boston, Tampica, Tunnelton, and Vallonia Quadrangles.

The general topography of Washington County is shown in Figure 7. Most of the soil in Washington County is on uplands and is moderately sloping to very steep. The soils on terraces and flood plains generally are nearly level or gently sloping. The highest point of Washington County reaches 1050 feet above sea level, which is an area of Franklin Township about 0.5 mile south of State Highway 56 and one mile northwest of New Philadelphia. The minimum altitude in the county is less than 490 feet above sea level. It is in an area of Brown Township where the East Fork of the White River leaves the northwest corner of the county (1).

(CONTINUED)

GEOLOGY OF WASHINGTON COUNTY

Washington County lies largely within the unglaciated area of the State; only a small area in the northeastern part of the county is covered with glacial drift (4). Washington County is located on the west flank of the Cincinnati Arch, between the arch and the deepest part of the Illinois Basin (Figure 8). Thus, most of the rocks of the county dip west-southwestward toward the basin. The regional dip is about 25 to 30 feet per mile (less than a third of a degree). However, the direction and magnitude of dip will vary in places; sometimes the direction even reverses due to anticlinal structures.

The surface deposits of Washington County are composed of bedrock of Mississippian age (Figure 9), and unconsolidated materials of the Tertiary and Quaternary periods. The bedrock in northern, northeastern, and eastern parts of the county are covered by till, sand and gravel deposited by Illinoian glaciers during the Pleistocene Epoch. During Wisconsinan times, outwash from glaciers entered the northern part of the county and formed a valley train in the East Fork (and tributaries) of White River. Finally, deposits of alluvium of Recent age ranging from a few feet to a few tens of feet covered most of the lake deposits and the valley bottoms of the county. These deposits consist mainly of clay, silt, sand and gravel.

Most of Washington County is covered by residual soils developed on bedrock. The oldest rocks exposed are those near the base of the Mississippian section.

The Mt. Carmel Fault which crosses the northern boundary of the county is the notable structural feature of Washington County. It probably formed in the early stages of formation of the Cincinnati Arch and the Illinois Basin. It is a normal dip-slip fault with an approximate dip of W. The eastern block is upthrown with respect to the western side. Vertical displacement is estimated to be between 80 and 175 feet. No movement has been recorded

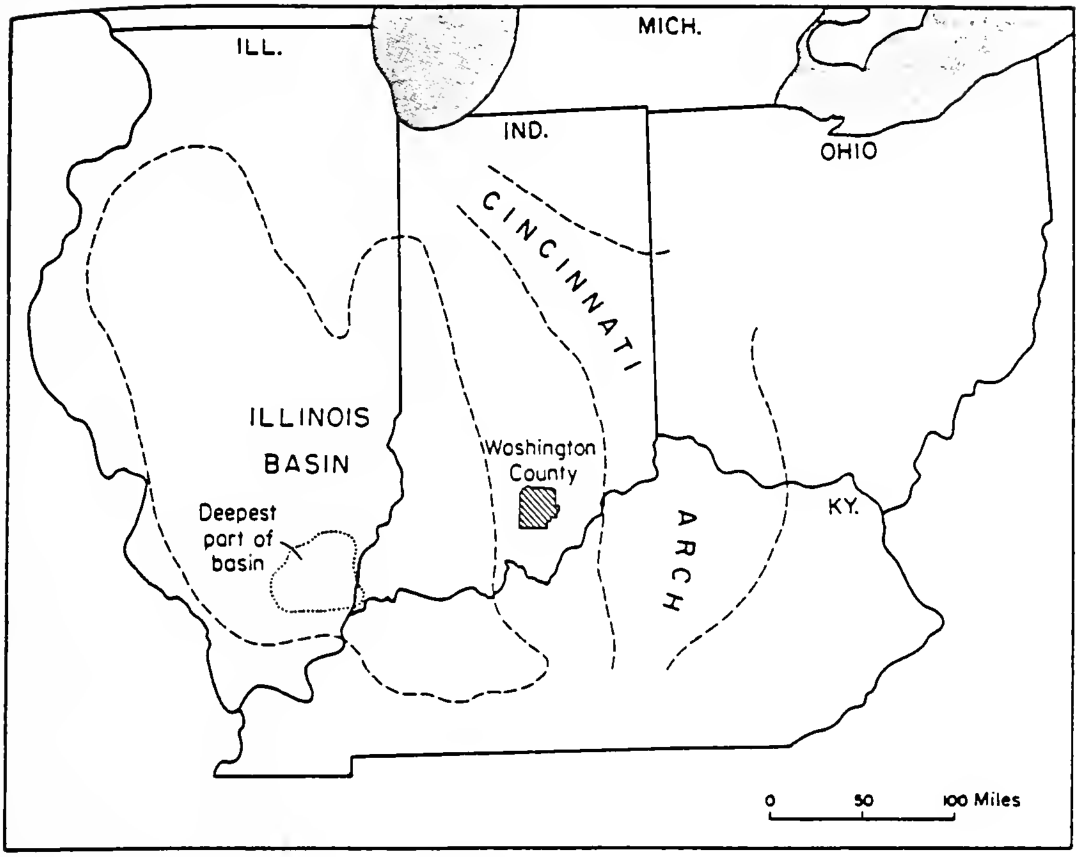

FIGURE 8. MAP SHOWING POSITON OF WASHINGTON COUNTY IN RELATION TO THE ILLINOIS BASIN AND THE CINCINNATI ARCH (2)

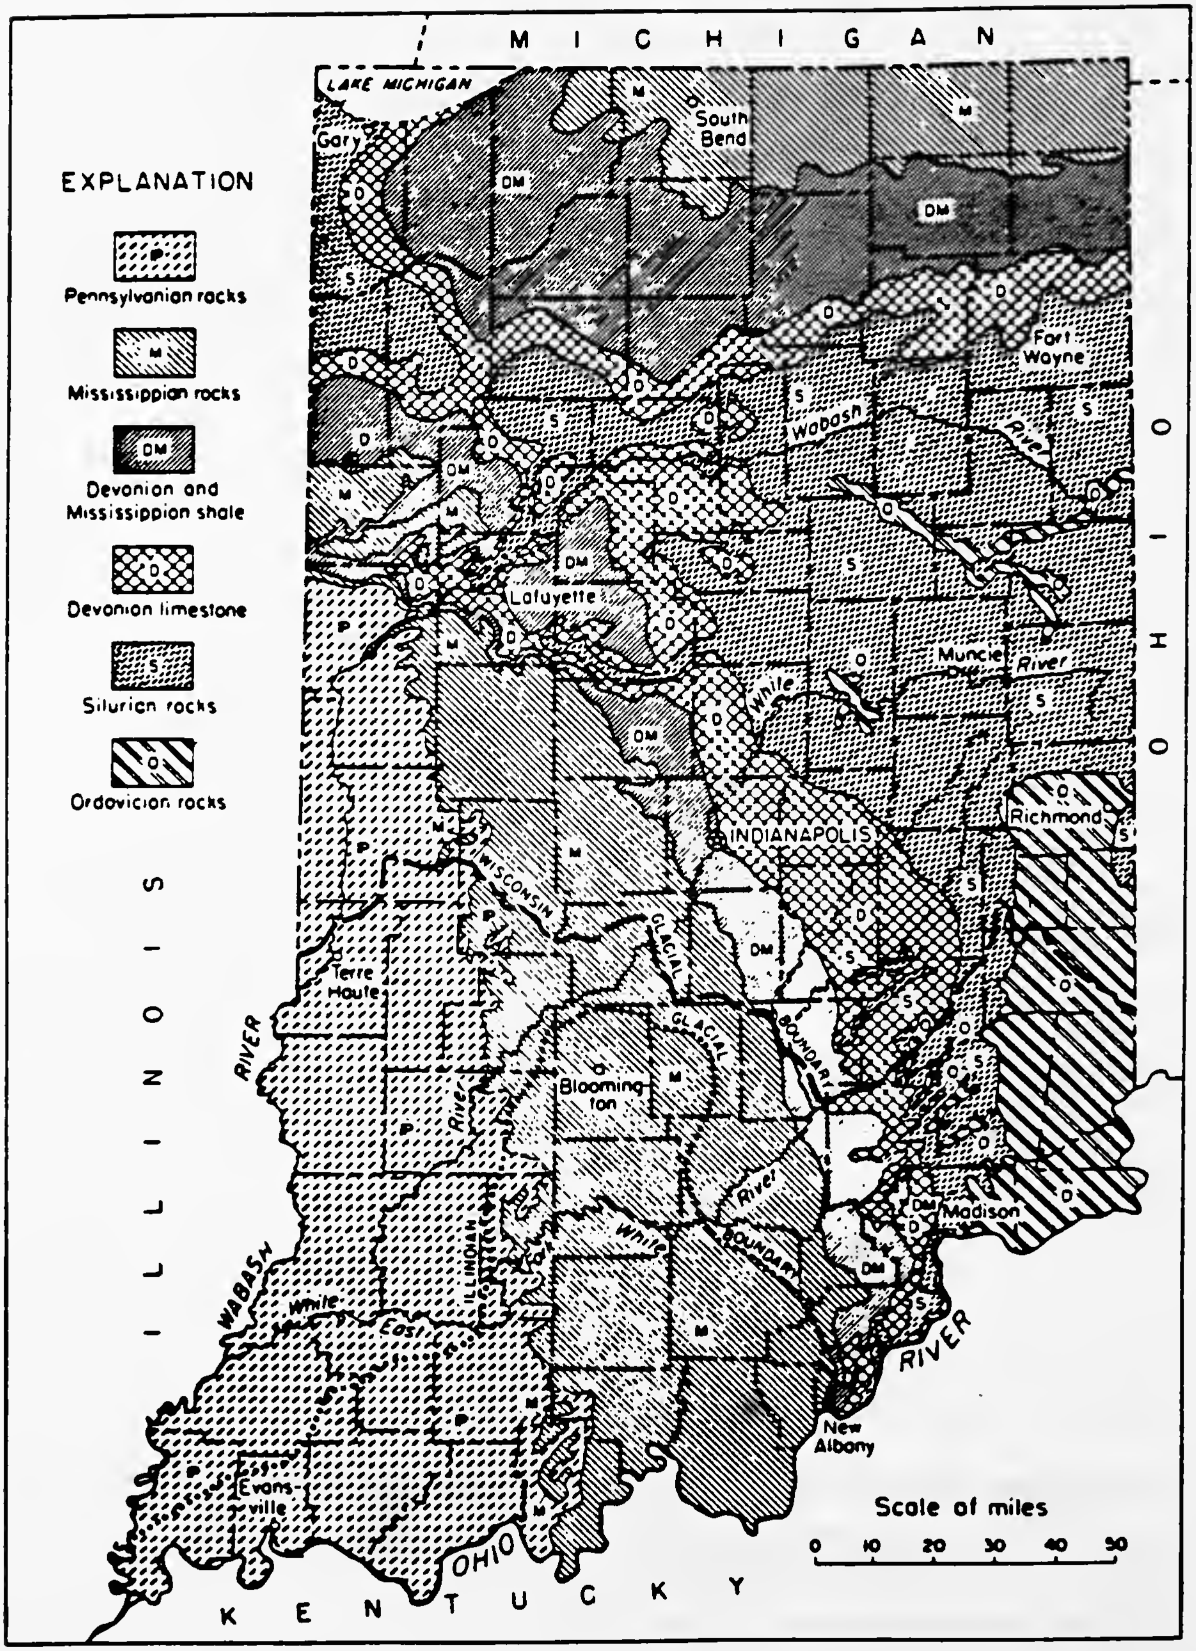

FIGURE 9. BEDROCK GEOLOGY OF INDIANA (20)

along this fault in historical time and, indeed, no indication exists of post-Paleozoic movement (5). The fault is no longer active and represents no seismic hazard to the area (6).

BEDROCK GEOLOGY

The bedrocks of the Washington County lie entirely within the Mississippian System as shown in Figure 10. This figure illustrates the disposition of the bedrock units as they would appear today if there were no unconsolidated deposits present to cover them up. They contain exposed formations ranging from the Borden Group (early-middle Mississippian) to the West Baden Group (late Mississippian).

Near the base of the Mississippian System is the Borden Group. It is named for the town of Borden in Clark County, and consists primarily of gray argillaceous shales and siltstones and some thin limestones and thin fine-grained sandstones. Rocks belong to the Borden Group are found in the eastern and northern parts of Washington County. The group is only 600 feet thick in Washington County, about 300 feet of which is exposed at the surface (2).

Sanders Group, consisting mostly of coarse-grained fossiliferous limestone, overlies the Borden Group. It is found in a curvilinear belt extending from the southeast to the northwest part of the county. The Sanders Group consists of the Harrodsburg Limestone in its upper part and the Salem Limestone in its lower part. The Harrodsburg Limestone, 60 to 80 feet thick in Washington County, was named for the town of Harrodsburg of Monroe County, whereas the Salem Limestone was named after the town of Salem, Washington County. Within Indiana, the outcrop belt of the Salem Limestone extends from the bluff of the Ohio Valley northward through Washington County (7). The Salem Limestone is 60-90 feet thick in Washington County, and has been used commercially for building stone in Washington County as well as in Lawrence and Monroe Counties.

(CONTINUED)

Overlying the Sanders Group is the Blue River Group. The Blue River Group, named for the Blue River, comprises the bedrock in the western and southern parts of Washington County. It is mostly fine-grained limestone and has a thickness of 275 feet (2).

The Blue River Group is composed of three formations: the St. Louis Limestone, the Ste. Genevieve Limestone, and the Paoli Limestone, in ascending order. Among them, the St. Louis Limestone is more susceptible to solution by ground water than most other formations in Washington County. In the regions underlain by the soluble St. Louis Limestone, undulating karst topography is well developed, and numerous sinkholes are common. Also in this region, most of the water is drained by underground streams flowing through cavernous limestone.

Finally, the West Baden Group, named after the town of West Baden in Orange County, overlies the Blue River Group. It contains an alternating sequence of relatively thin sandstones, shales, and limestones. The Group is present in the southwest corner of the county as well as in some isolated spots in the central part of the county. A few sinkholes exist in the southwest corner, and they are considered to be reflection of subsurface solution features developed in the underlying older limestones (2).

The bedrock topography of Washington County is shown in Figure 11. The lowest bedrock altitude exists in the northern part of the county, which corresponds to the East Fork of White River and the tributary Muscatatuck River. The valley is now an extensive plain, and has been filled with Kansan, Illinoian and Wisconsin glacial outwash and Recent nonglacial stream alluvium.

In the central and southern parts of Washington County, the channel of the Blue River may cut down as much as 100 feet or more into the surrounding bedrock. In some places along the Middle and South Forks of Blue River, bedrock thinly covered by a few feet of glacial

material is found under terrace surfaces. Thus, bedrock benches are found here at about the same level as valley-train terraces (2).

TERTIARY AND QUATERNARY GEOLOGY

The unconsolidated deposits of Washington County are illustrated in Figure 12. The unconsolidated sediments in Washington County are of the Tertiary and Quaternary Systems. The glacial drift of Illinoian and Wisconsin ages is present in the north and east, whereas residual soils of Tertiary to Quaternary period are present in the west and south. Recent alluvium is also found in most stream valleys.

Most of the deposits of Tertiary age in Washington County are residual soils. However, the depositional timespan of these soils may range from early Tertiary to Recent. Weathering of bedrock and deposition of rock residue is the main reason for the formation of these residual soils. The red clay found in these residual soils probably is the residuum of decomposed Mississippian argillaceous limestone, whereas the sands are probably derived from the sandstones in West Baden Group (2).

The unconsolidated deposits of the Quaternary Period in Washington County include sediments of Illinoian, Wisconsin, and Recent ages. The Illinoian and Wisconsin glacial boundaries are shown previously in Figure 6.

The Illinoian glacial boundary extends into the northern and eastern parts of Washington County. As shown in Figure 12, sediments of Illinoian age are found in the northeast corner of Washington County as surface deposits (or under the surface deposits) on the flood plain of the Muscatatuck River and its tributaries. They consist of two parts: tills and drifts of Jessup Formation, and lake clay, silt and sand of the Lacustrine Facies of Atherton Formation. The thickness of this layer may be as much as 100 feet in some places. Besides, many of the stream

(CONTINUED)

valleys in the county, especially the Upper Forks of Blue River and the tributaries of the East Fork of White River are underlain by alluvial silt, sand and gravels, which are classified as Prospect Formation in Indiana (2). For example, the South Fork of Blue River contains some valley-train material, and scattered glacial pebbles are found in the streambeds of the other two Forks of Blue River.

As shown in Figure 6, the Wisconsinan glaciation did not extend as far south as Washington County. However, in Wisconsin time and pre-Wisconsin time the East Fork served as a meltwater channel, and thus is filled with outwash deposits consisting of clay, sand, and silt to depths of 50 to 100 feet. Outwash of Illinoian and older material may be preserved under these deposits; however, much of the pre-Wisconsin glacial sediments have probably been stripped away by erosion before Wisconsin age (2).

During Wisconsin time the valley-train built up in the East Fork of White River served as a dam to the incoming Muscatatuck River and other branches. Thus the Muscatatuck River and other tributaries are ponded. The lake deposits of Muscatatuck River valley are 40 to 70 feet thick (2).

There are also sand dunes of Wisconsin age found in the northern part of the county along the banks of East Fork and some of its tributaries. Sand also occurs as a thin veneer over terraces in many places. Loess of Wisconsin age is also very common in Washington County.

Among the Recent age sediments flood-plain silts, sands and clays cover most of the stream valleys of Washington County. In the northern part, alluvium of Recent Age ranging from 10 to 25 in thickness covers most valley-train deposits of the East Fork and the lake deposits of the Muscatatuck River. In the southern part of the county, stream gravels and flood-plain clays and silts also filled the Blue River and its three branches. The thickness of these deposits varies from place to place (2). The total thickness of unconsolidated deposits

in Washington County is shown in Figure 13. It can be seen that the thickness is less than 50 feet in most parts of the county. However, the thickness may reach 150 feet along the northern border of the county, that is along the East Fork valley and the Muscatatuck River valley.

LANDFORM-PARENT MATERIAL REGIONS

The soils in Washington County consist of Quaternary unconsolidated sediments and residual soils derived from limestone, siltstone, sandstone and shale bedrock. For mapping and discussion purpose, these materials have been classified into five groups according to parent material and landform in the following section. They are residual soils, glacial drift, fluvial drift, lacustrine drift and eolian drift. Then they are further subdivided into smaller groups for more specific description.

Each landform-parent material region is characterized by its overall extent, surface morphology and character, and general soil profile. Classification based on both the United States Department of Agriculture (USDA) textural designation and the American Association of State Highway and Transportation Officials (AASHTO) System is included. In addition, the agricultural soil series that form in each of the landform units are also indicated. Boring numbers, which correlate with the classification test results tabulated in Appendix A, are shown on the Engineering Soil Map for each soil unit. The physical and chemical, and engineering index properties of these soils are presented in Appendices B and C.

On the accompanying Engineering Soil Map, the landform-parent material regions of Washington County and the representative soil profiles of each of the regions are presented. Plus signs (+) are used to represent loess cover. In order not to make the map too complicated, a plus sign (+) is given only at the center of each section if a greater part of that section is covered by loess. Similarly, letter s is used to represent considerable number of sinkholes, and letter k is for well-developed karst topography. The engineering properties of different regions are briefly addressed in the following text. The discussion provides the investigator with a general idea of the engineering problem and engineering consideration associated with each landform-parent material region. For more specific information, the

reader is referred to the soil boring data in Appendix A, and the soil investigation reports in the reference list. Nevertheless, local variation is possible within any given region, and the information contained in this report should be used for preliminary design only.

RESIDUAL SOILS

The residual soils in Washington County are developed from the decomposition of rocks such as sandstone, shale, siltstone and limestone. They constitute the surface soils or near-surface soils for most parts of the county except the stream valleys. The thickness of these residual soils is highly variable, especially in the limestone region.

Sandstone, Shale and Siltstone Residuum

Residual soils of sandstone, shale and siltstone are found in the northern and eastern parts (Norman Upland) of the county. Small areas of residuum of sandstone, shale and siltstone are also found in the southwest corner (Crawford Upland), which is very likely derived from rocks of the West Baden Group. Parts of these residual soils are covered by thin blanket of loess.

This map unit makes up about 24 percent of the county. Erosion caused by overgrazing is the major hazard in this area. The soils in this area are generally unsuited to sanitary facilities and dwellings. Typically, the surface layer is silt loam or loam. The subsoils consist of silt loam, silty clay loam, clay loam, and loam (1). From boring data, the surface and subsurface soils developed along these residual soils can be classified as A-4(8) and A-4(6).

The agricultural soils that form on the sandstone, shale and siltstone residuum are Wellston, Zanesville, Berks-Weikert Complex, Elkinsville, Gilpin, Gilpin-Berks, Gilpin-Berks-Ebal Complex, and Peoga series. The liquid limits lie in the range of 20 and 75,

and plasticity indices ranges from NP to 20 (none to medium degree of plasticity) according to Appendix C.

Boring number 48, 49, and 52 are located in this region.

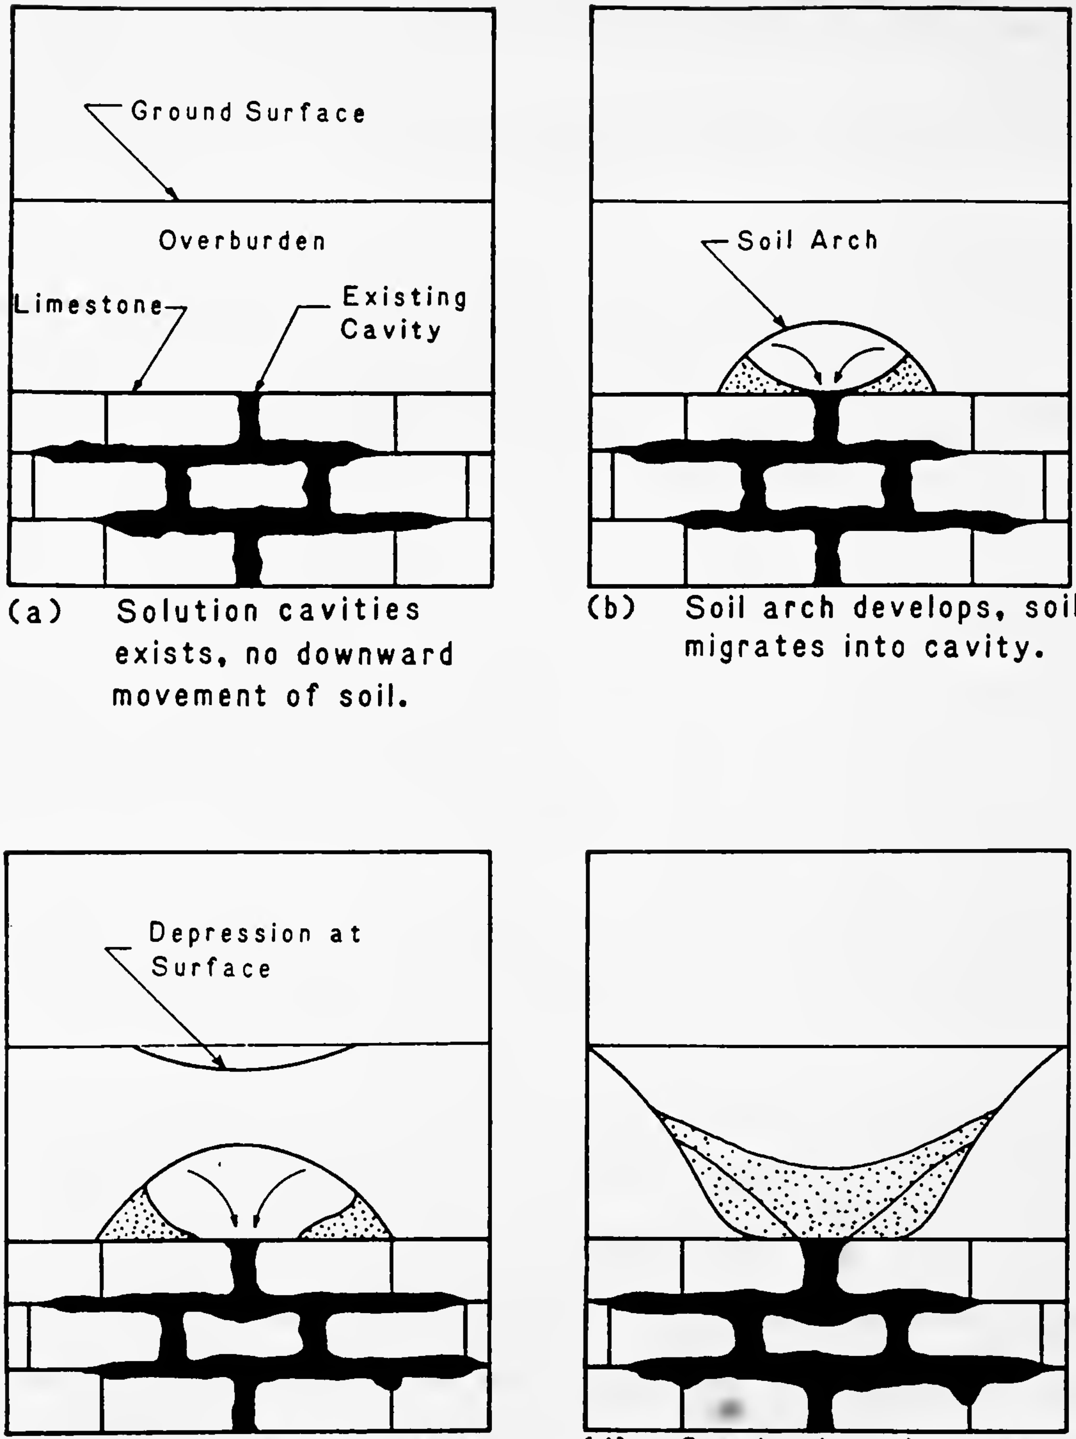
Limestone Residuum

The limestone residuum occupies the largest portion of Washington County, and is blanketed by a thin loess cover. Limestone residuum is the dominant soil in Mitchell Plain, and is also found on the Crawford Upland and the Norman Upland (6).

In the Mitchell Plain, which is unglaciated, the dominant landforms are rounded knolls with intervening lowlands, sinkholes, and associated depressions. Small areas are dissected by small drainageways. The surface drainage is through sinkholes and associated subterranean channels which are the indications of underlying limestone. As mentioned earlier, the St. Louis Limestone in this area is most susceptible to solution by ground water and thus may have most of the sinkhole developments.

A unique topography called karst can be seen in this area, especially on exposed limestone. The term karst is applied to special topography that is formed on limestone, gypsum, and other rocks by dissolution (8). It is characterized by numerous depressions, a notable lack of surface drainage, and many caves and subsurface openings (6). These underground cavities and induced sinkholes are the major problems in karst terrains.

Sinkhole formation is intensive in the southern and southwestern part of the county, especially in the area surrounded by the towns of Hardinsburg, Livonia, Becks Mills, Fredericksburg. Figure 14 illustrates the process of sinkhole development. A sinkhole density map for Washington County is prepared from the drainage map simply by counting the number of sinkholes in each section, and this is shown in Figure 15. Since most water is drained through



(a) Solution cavities exists, no downward movement of soil.

(b) Soil arch develops, soil migrates into cavity.

(c) Arch increases in size, subsidence evident at surface.

(d) Overburden migrates downward, dish-shaped depression at surface.

FIGURE 14. PROCESS OF SINKHOLE DEVELOPMENT (6)

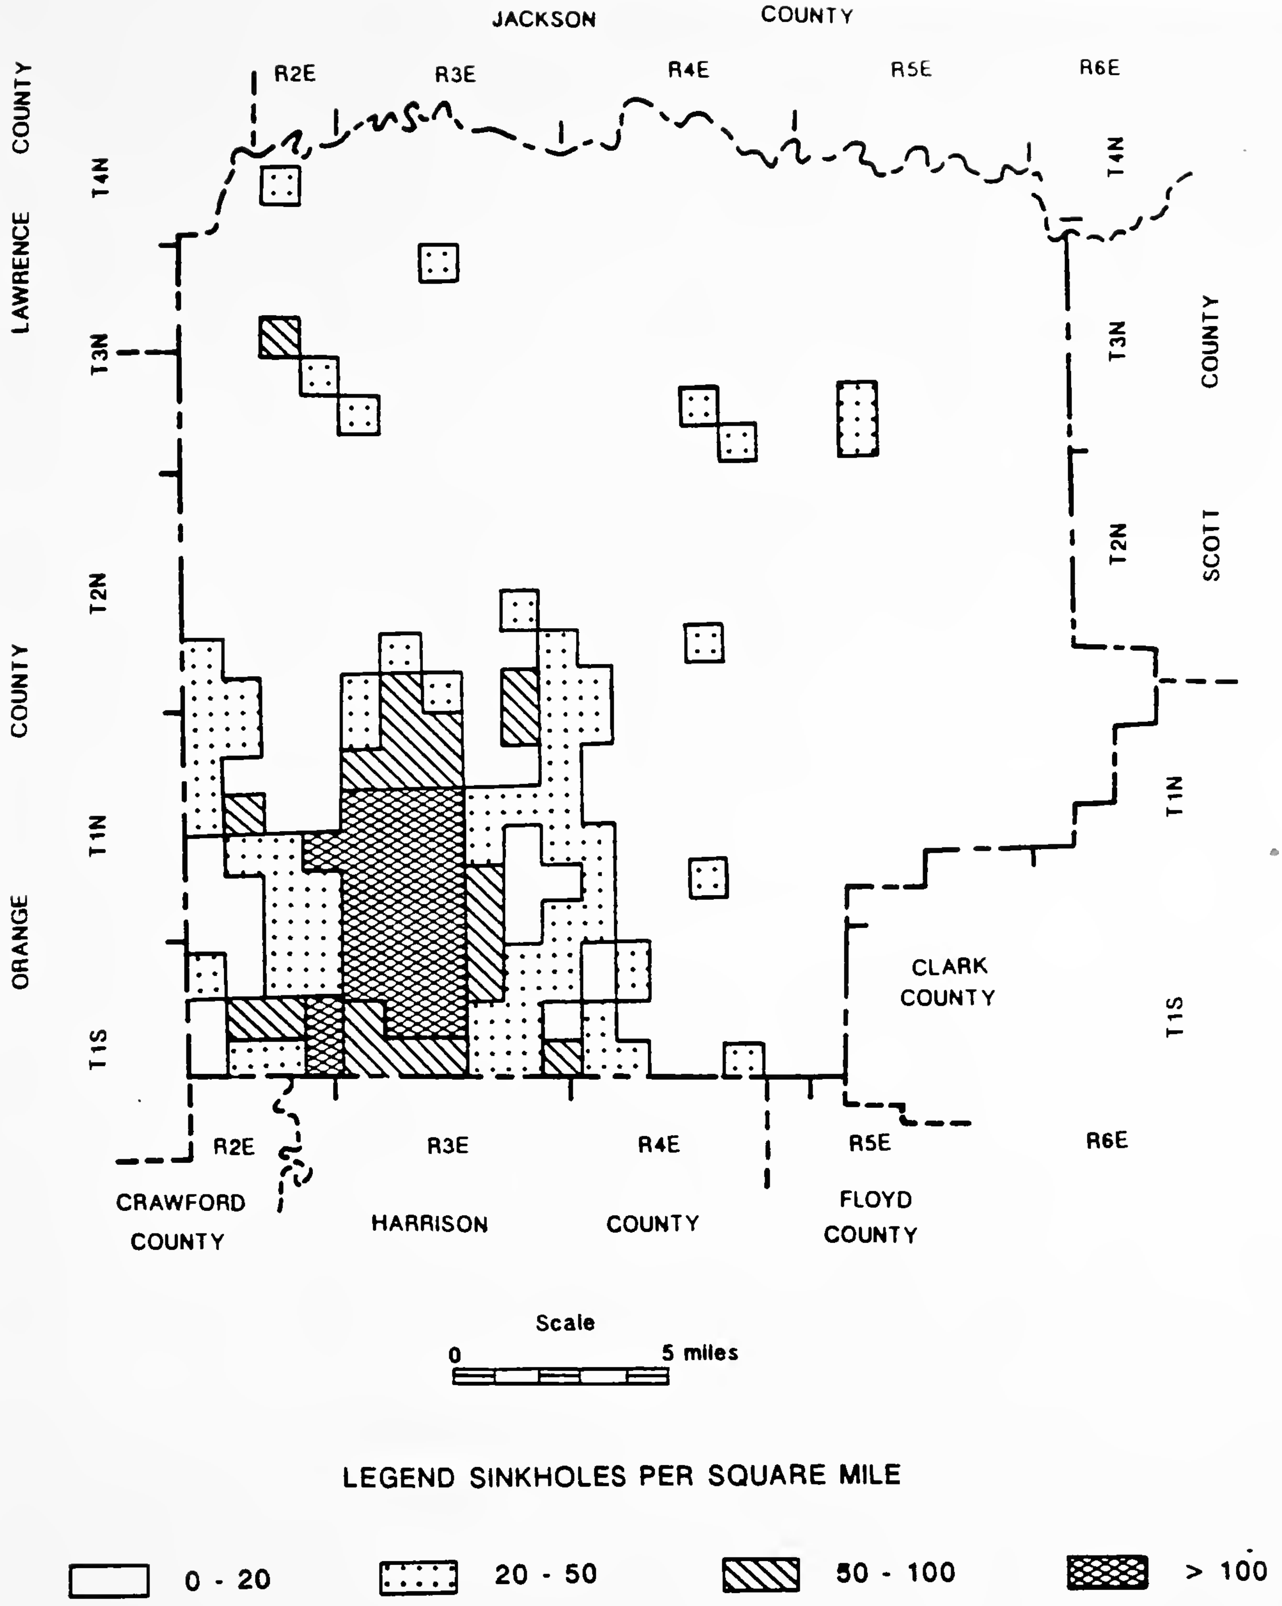


FIGURE 15. SINKHOLE DENSITY MAP OF WASHINGTON COUNTY (14)

sinkholes and underground channels, surface streams are not well developed. The Blue River and Lost River have cut into the Mitchell Plain (limestone residuum) deeply and form deep, narrow valleys. Thick residuum is common on the drainage divide between sinkholes and between valleys (9). On sideslopes, soils are usually thinner at the upper part than at the lower part.

This map unit makes up about 60 percent of the county. Erosion is the major concern in this area. Overgrazing is the major problem in controlling the erosion because the plant density is reduced. About 73 % of this area is fairly well-suited to sanitary facilities, dwellings, and recreational uses. Very minor extent of rock outcrops can be found on side slopes. Typically, the surface layer is silt loam. The subsoil is silt loam and silty clay loam in the upper part; silty clay loam, silt loam or silty clay in the next part; and silty clay or clay in the lower part (1). The wide variation of soil profile in this landform is shown on the attached map. From the boring data available in this area, the RQD values of the bedrock range from 20 to 95. The liquid limits range from 21 to 92, whereas plasticity indices fall between NP and 65. The surface and subsurface soils developed along these residual soils consist of clay, silty clay, silty loam, silty clay loam, clay loam, loam, and sandy loam. They can also be classified as A-6(0-16, 18, 19), A-7-6(12, 14-20, 33), A-4(0-8), A-2-6, A-2-4, and A-7-5(45). Fragments of limestone and chert are often encountered in these soils. The underlying bedrock is interbedded limestone and shale.

The agricultural soils that form on limestone residuum are Bedford, Bromer, Caneyville-Hagerstown, Caneyville-Rock Outcrop Complex, Crider, Crider-Frederick, Frederick, Frederick-Baxter Variant Complex, Hagerstown, and Hagerstown-Caneyville series.

Boring numbers 1-16, 20-47, 58-225 are located in this region. According to the boring logs, the soil profile in limestone residuum is very irregular and erratic. This is probably due to the fact of irregular weathering and the formation of karst topography.

Engineering Considerations in Residual Soils

The residual soils, either derived from limestone or sandstone-shale, are susceptible to weathering. In southern Indiana, the residual soils developed from limestone and shale are relatively deep, and it is seldom that the unweathered rock formations are within 10 feet of the ground surface. However, chert fragments are present in these residual soils at almost every location and depths.

In the sandstone-shale area, care should be taken on fill material of embankment in highway construction. Shale fragments are unsuited because of their low slaking durability and difficulty in compaction. A mixture of sandstone and shale fragments is also unfavorable.

In limestone residuum area, karst topography and sinkholes are the major concerns. Actually they are the major geologic hazards. The avoidance of karst areas is highly desired because the construction and maintenance of highway in karst area is a challenge. The unpaved ditchlines are very prone to sinkhole formation and collapse. To solve this problem, engineers usually treat the ditchlines with an impervious material such as concrete to prevent sinkholes development and enlargement, and backfill induced sinkholes with chunk rock (8). Although this repair of sinkholes is always necessary to prevent further collapse, the fill of sinkholes may alter the subsurface and surface drainage features. Thus, special filling material and construction technique are needed.

In addition, sinkholes and cavities are also dangerous to shallow foundations. Deep foundations founded on solid rock are recommended for moderate to large structures. It is

also recommended that extensive subsurface exploration is necessary before design, especially in mantled-karst areas where the overlying deposits obscure the potential of subsurface erosion and sinkhole development. The exploration program may consist of the use of standard penetration test borings, electric piezocone soundings, ground penetrating radar, and piezometers to document the subsurface condition (8). A variety of geophysical methods are also available to detect the location of cavities such as electrical resistivity, surface seismic, crosshole seismic, acoustic resonance, electromagnetic and microgravity methods (8). In planning cut and fill for highways, it is also necessary to pay attention to the rugged surface and variable depths to bedrock.

In karst areas, seepage is also likely to occur which drains lakes and ponds. Another greater danger comes from the leakage of sewage effluent storage pond which can cause the contamination of groundwater. Under such circumstances, a grouting program might be necessary.

GLACIAL DRIFT

The bedrock in northern, northeastern and eastern parts of the county is covered by till, sand and gravel deposited by Illinoian glaciers. Parts of these glacial drift materials were later covered by outwash of Wisconsin and alluvium of Recent age; the others are still exposed at the ground surface. As it can be seen in the accompanying map, most of the glacial drifts are located in the northeast corner of the county. The largest glacial till covered area is located south of the town of Little York. In Washington County, the entire glacial drift is covered by loess.

The map unit of glacial drift makes up one to two percent of the county. Erosion can occur if the plant density is reduced. The soils in this area are poorly suited to sanitary facilities

and dwellings. Typically, the surface layer is silt loam, and the subsoil consists of silt loam, loam and clay loam (1). From the boring data in Appendix A, the liquid limits of these soils range from 27 to 43, and plasticity indices from 2 to 24. The surface and subsurface soils developed along these glacial drifts consist of clay, silty clay loam, silt loam, and loam. They can also be classified as A-4(0,8), A-7-6(14), and A-6(10).

The agricultural soils that form on glacial drift are Avonburg, Cincinnati, Hickory, and Rossmoyne series.

Boring numbers 51, 55, 56, 57 are located in this region.

Engineering Considerations in Glacial Drift

In Washington County, most of the glacial drifts are of Illinoian Age. The soils have been weathered to a considerable depth so that the surface soils are predominantly silts (3). Thus, they are too weak for highway subgrade. Either replacement or improvement of the soils is necessary. The possibility of frost-heaving damage to highway pavement is quite low in spite of the presence of silts. This is probably due to warmer climate and uniform heaving (3). In addition, great difficulty may be expected in construction during wet season in Illinoian drift area, where silts are prevalent. These silts are unstable at a moisture content even one percent above their critical optimum moisture content. If sheepsfoot or tamping rollers are used to recompact such soils, great care should be taken in constructing the fill with a considerable crown (3).

The silts in Illinoian drift area are also susceptible to erosion, particularly the loess cover. The glacial drift generally has poor gradation, and sometimes the buried channel under surface deposits can cause serious engineering problems during highway construction.

FLUVIAL DRIFT

Fluvial drift appears in two landforms in Washington County. They are flood plain and terrace.

Flood Plain

Soils of flood plain generally are adjacent to the streams and in the lower areas away from the streams. There are flood plains developed along the four river systems. In general, the flood plains of the White River system are larger than those of the other three river systems. The Middle Fork and South Fork of Blue River also have flood plains of considerable extent. However, the main channel of the Blue River cuts into the surrounding bedrock as deep as 100 feet. Thus, only limited areas of flood plains have developed along the Blue River channel. Besides, there is no loess cover on flood plain.

The largest flood plain appears in the northeast corner of the county. It is associated with the Muscatatuck River, one of the branches of the White River system. In the southwest corner of the county, there are hanging flood plains developed due to the presence of sinkholes and underground drainage.

In particular, the soil profile of flood plain along the East Fork of White River has courser grains in the lower part because the velocity of meltwater of Illinoian glacier is much higher than the present stream (6).

This map unit makes up about 10 percent of the county. Wetness and flooding are the major concerns in this area. The soils are generally unsuited to sanitary facilities and dwellings. Typically, the surface layer and the subsoils are silt loams (1).

From the boring data, the surface and subsurface soils developed along these flood plains consist of clay loam, silty clay loam, silty clay (with gravel), clay, limestone (with shale), sandy loam (with gravel), silty loam, loam, and sand. Or they can be classified as A-2-6(0), A-2-4(0),

A-4(1, 4, 6, 8), A-6(5, 6, 8), A-7-6(6, 12, 13, 14, 15, 16, 17, 19, 25). The liquid limits fall between 24 and 55, and the plasticity indices range from NP to 25. The underlying bedrock is limestone or shale.

The agricultural soils that form in these areas are the Bonnie, Burnside, Cuba, Haymond, Nolin, Stendal, and Wakeland series.

Boring numbers 17-19, 50, 53, 54, 226-263 are located on flood plains.

Terrace

This map unit consists of soils on terraces and the higher rises away from the stream. There are several reasons for the formation of terraces in Washington County. Some of them are alluvial terraces, others are lacustrine terraces which are formed in choked (by valley-train) and ponded stream valleys during Wisconsin age. Similarly, there are some terraces associated with outwash of Wisconsin age. These terraces of different origin are grouped together because they are closely related and sometimes adjacent to one another.

Terraces are distributed along the stream valleys of the four major river systems. Some of the terraces are covered by eolian materials, or sand dunes (but not loess). The largest terrace is located on the northern border where the Muscatatuck River enters the East Fork of White River. Its formation is related to water action of the Muscatatuck River. There are also lacustrine deposits because this area was ponded during Wisconsin age.

Terraces make up about 4 percent of the county. Wetness and erosion are the major concerns. The soils are unsuited to sanitary facilities and dwellings. Typically, the surface layer is silt loam or silty clay. The underlying materials are silt loam, silty clay loam, or silty clay (1).

The agricultural soils that form in these areas are the Alvin, Markland, Chetwynd, McGary, Montgomery, Pekin, Bartle, and Zipp series. According to Appendix C, the liquid limits are smaller than 65, and the plasticity indices range from NP to 42.

No soils boring reports are available for terrace areas at the time of preparing this report.

Engineering Considerations in Fluvial Drift

Fluvial sediments are usually layered. Therefore, the permeability in the horizontal direction is much greater than the vertical direction. The composition is highly variable, but the soil typically is normally consolidated (10).

The engineering problems associated with flood plain are their low shear strengths, high compressibility, and the danger of scour (6). As mention earlier, wetness and flooding are the major concerns. It is also difficult to construct buildings or bridges because of the underlying soft material.

For terrace, high potential of erosion is the major engineering problem, especially on the side slopes. Moreover, terraces are very prone to circular type of failure. Usually these failures occur after heavy rainfall.

Excavation is a problem in fluvial drift for both flood plains and terraces. This is mostly due to high groundwater table. A dewatering program should be included in construction.

LACUSTRINE DRIFT

Lacustrine drift occurs in the form of lacustrine plain in Washington County. Besides, there are also lacustrine deposits found in terrace areas as discussed earlier, and will not be repeated here.

Lacustrine Plain

Lacustrine plains are present in the northeast corner of the county. Most of them are very small in areal extent, and they are all related to the tributaries of the Muscatatuck River. All the lacustrine plains have a thin loess cover. The major lacustrine plain occurs around the town of Little York.

Lacustrine plain makes up 1 or 2 percent of the county. Erosion and wetness are common concerns in this area. The soils are poorly suited to sanitary facilities and dwellings. Typically, the surface layer is silt loam, whereas the subsoils are silt loam, silty clay loam, and silt loam (1).

The agricultural soils that form in these areas are the Dubois, Haubstadt, and Otwell series. Their liquid limits are smaller than 50, and they have plasticity indices ranging from 3 to 30 (1).

No soils boring reports are located on lacustrine plains at the time of preparing this report.

Engineering Considerations in Lacustrine Plain

The soils of lacustrine plain are moist in nature. They have low shear strength and high compressibility. Therefore, they are prone to large settlement if loaded. The sediments of lacustrine origin in Washington County have a silt texture in contrast to the clay-like texture in the northern part of the state. Pavement design problems are also less than the northern counties (3).

EOLIAN DRIFT

The eolian deposits actually almost cover the entire surface of the Washington County. They are in the form of loess veneer and sand dunes. Since loess cover is relatively thin, it is classified according to underlying materials and discussed in the previous section. Besides, it

is not shown as an independent map unit on the Engineering Soil Map, but is identified by a textural symbol (+). In the following section only sand dunes will be discussed.

Windblown Sand Deposit

Sand dunes are found on the area adjacent to the East Fork of White River. Some of them occur on terraces, which has been discussed earlier. Others are deep windblown sand deposits. Both of them are probably migrating sand dunes in Wisconsin age.

The agricultural soil that forms on windblown sand deposits is Bloomfield series. The liquid limits are smaller than 20, and the plasticity indices lie in the range of NP and 3 (none to slight degree of plasticity).

No soils boring reports are available for windblown sand deposits at the time of preparing this report.

Engineering Considerations in Windblown Sand Deposit

Windblown sand deposits are always in a loose state because of their uniform gradation and low speed of deposition (10). However, the soil profile of windblown sand deposit in Washington County may be erratic and vary from place to place since no boring log is available.

Engineering Considerations in Mantled-loess Area

Loess has sufficient strength while it is dry. The highway cut slope in loess can stand vertically if no water is added. Localized failure is possible on loess slope due-to freeze, thaw and desiccation. Loess usually is loose-textured and has high porosity. For the loess soils from midcontinental U.S., the pore space is generally composed of continuously connected pores with a model pore size of about 5 to 10 (11). Moreover, almost all the pores are ink bottle

pores, i.e., the pore throat to pore body ratio is relatively small. In Indiana, loess may be fairly thick in some localities. However, most of the loess veneer has only 5 to 10 feet in thickness (3).

MISCELLANEOUS

Pits and Quarries

A number of quarries from which limestone has been removed are seen around the town of Salem in the central part of the county. There is also an abandoned sandpit in the southeast corner of the county.

Marsh and Swamps

A few marshes are seen around the county and are shown on the Engineering Soil Map. The marsh and swamp soils are characterized by their low strength and high compressibility. Furthermore, they become weaker with time and are generally corrosive (highly acidic) to foundation material (10).

SUMMARY OF ENGINEERING CONSIDERATIONS IN WASHINGTON COUNTY

Table 5 is the summary of engineering considerations for different landform-parent material regions in Washington County. Each landform-parent material and their associated engineering problems are included in the table. However, the ranking shown in the table is recommended to be used as a general guideline only. Site specific investigation is always needed for any project in Washington County.

APPENDIX D

STATISTICAL STREAM FLOW DATA FOR SELECTED STREAMS IN WASHINGTON COUNTY (39)

APPENDIX D-1. STATISTICAL STREAM FLOW DATA FOR WEST FORK BLUE RIVER (39)

03302680 WEST FORK BLUE RIVER AT SALEM, IN

LOCATION.--Lat 38°36'19", long 86°05'40", in SW¼SE¼ sec.17, T.2 N., R.4 E., Washington County, Hydrologic Unit 05140104, on left bank at downstream side of bridge on East Market Street, 0.35 mi east of County Court House in Salem, 6.0 mi upstream from Hoggatt Branch, and 6.9 mi upstream from mouth.

DRAINAGE AREA.--19.0 mi^2.

PERIOD OF RECORD.--July 1970 to September 1985. Prior to December 10, 1970, nonrecording gage at site 0.55 mi downstream at datum 5.04 ft lower. Low-flow records not equivalent due to effluent from factory entering stream from right bank between sites.

GAGE.--Water-stage recorder. Datum of gage is 713.00 ft above National Geodetic Vertical Datum of 1929.

AVERAGE DISCHARGE.--15 years, 25.0 ft^3/s, 17.87 in/yr.

EXTREMES FOR PERIOD OF RECORD.--Maximum discharge, 5,400 ft^3/s May 1, 1983, gage height, 13.14 ft from rating curve extended above 900 ft^3/s by a step-backwater analysis; minimum daily, 0.02 ft^3/s Sept. 24, 1970.

DURATION TABLE OF DAILY MEAN DISCHARGES FOR YEAR ENDING SEPTEMBER 30

APPENDIX D-2. STATISTICAL STREAM FLOW DATA FOR BLUE RIVER (39)

03302800 BLUE RIVER AT FREDERICKSBURG, IN

LOCATION.--Lat 38°26'02", long 86°11'31", in NE¼NW¼ sec.16, T.1 S., R.3 E., Washington County, Hydrologic Unit 05140104, on downstream side of bridge on U.S. Highway 150 at Fredericksburg, 0.5 mi downstream from South Fork Blue River, and at mile 57.1.

DRAINAGE AREA.--283 mi^2, of which 76.9 mi^2 does not contribute directly to surface runoff.

PERIOD OF RECORD.--June 1968 to September 1985.

GAGE.--Water-stage recorder. Datum of gage is 590.00 ft above National Geodetic Vertical Datum of 1929.

AVERAGE DISCHARGE.--17 years, 342 ft^3/s, 16.41 in/yr.

EXTREMES FOR PERIOD OF RECORD.--Maximum discharge, 13,500 ft^3/s May 2, 1983, gage height, 24.37 ft; minimum daily, 6.1 ft^3/s Oct. 18, 1968.

EXTREMES OUTSIDE PERIOD OF RECORD.--Flood of Jan. 21, 1959, reached a stage of 29.20 ft, from floodmark, on left upstream wingwall.
